

# NO-TILL WHEAT LONG-TERM EFFECTS

Lloyd Murdock, Jim Herbek, Jim Martin, John James, and Dottie Call

## **OBJECTIVE:**

The objective of this experiment was to verify the effects of no-till wheat and tilled wheat on the subsequent yield of soybeans and corn planted after wheat in a wheat, double-cropped soybean and corn rotation and measure differences in fertility and physical effects on the soil on a long-term basis.

## **METHODS:**

The experiment is at Princeton, Ky on a Huntington silt loam soil that is moderately well drained. Wheat was planted no-till and with tillage and the tillage plots were chisel plowed and disked twice. The plots were 10 ft x 30 ft. The trial was soil tested each year and fertilizer and lime applied according to University of Kentucky recommendations. N was sidedressed on corn at 150 lb/ac. Soybeans are planted no-till immediately after wheat harvest and no-till corn is planted the following year and wheat (tilled and no-tilled) is again planted after corn harvest.

## **RESULTS:**

### *Yields of Succeeding Crops*

The data (below) indicates that both no-till corn and no-till soybeans tend to yield more (4.6% for soybeans and 4.4% for corn) where the wheat is planted no-till. A statistically significant yield increase has been found about 50% of the time with corn and about 30% of the time with soybean.

These yield differences indicate that changes between the two systems have taken place with time and the changes favor the system which has only no-tillage wheat plantings in it. Research indicates that the reason for the difference is due to residue cover, soil moisture, soil physical changes and more importantly a

change in pore size distribution. There are more medium sized pores in the upper few inches of the soil that hold more plant available water.

### *Soil Changes*

There is no difference in the soil density between the systems. This indicates that there was no compaction of significance in either system. The soil strength, as indicated by penetrometer measurements, was higher in the exclusively no-tillage system. This and other soil measurements indicate that the soil structure has changed and has larger aggregates and more medium sized pores than the system that is tilled every second year for wheat planting.

Soil moisture measurements taken during the latter part of the growing season are higher in the true no-till system about half of the years and about the same as tilled the other years. When the soil moisture is higher, corn and soybean yields are usually higher in the no-till system. In the years when there is no difference in soil moisture, the yields are similar. The no-tilled soil can hold more plant available water but the rain must fall at the proper time for the advantage to express itself. In some years, it does and others it does not.

## **SUMMARY AND CONCLUSIONS:**

A true no-tillage system seems to have a favorable effect on the corn and soybean crops grown in rotation with the no-till wheat. When no-till wheat was grown, the average yields of no-till corn and soybeans had 4.6 and 4.4% greater yields, respectively, than when these crops were grown after tilled wheat. The soil changes include larger aggregates and more medium pores which result in more plant available moisture for these crops.

EFFECT OF WHEAT TILLAGE SYSTEMS ON THE YIELD OF SUCCEEDING CROPS		
Year	Wheat Tillage System	
	No-Till	Conventional
<i>Soybeans (bu/ac)</i>		
2003	66.6**	63.6
2002	30.7**	26.8
2001	35.3	34.1 N.S.*
2000	45.6	42.9 N.S.
